Abstract: In the assessment of food quality, geranyl acetone plays a crucial role as a volatile organic compound (VOC) biomarker for diverse agricultural products, while the ultralow concentration detection meeting application requirements has been barely studied. Herein, an iron (Fe)-doped WO$_{3-x}$ gas sensor was employed for greatly sensitive, selective, and scalable geranyl acetone detection. The results proved that precisely-regulated oxygen vacancy (O$_V$) and sophisticatedly-active electron transition of Fe-doped WO$_{3-x}$ nanoparticles were fulfilled by modifying the doping amount of Fe^{3+}, leading to the prominently enhanced sensitivity (23.47 at 6 ppm), low limit of detection (LOD) (237 ppb), optimal selectivity, and outstanding long-term stability. Furthermore, the enhancing mechanism of gas sensing performance was substantiated through density functional theory (DFT) calculation, while the practical application for the evaluation of spoiled cooked rice was conducted as well. This study demonstrates a reliable method for detecting a VOC biomarker in cooked rice, which can ensure food security and improve palatability of cooked rice.

Keywords: tungsten trioxide (WO$_3$); gas sensor; doping; geranyl acetone; room temperature; density functional theory (DFT)

1   Introduction

Geranyl acetone with *magnolia* and green odor [1] is an essential biomarker for fragrance and freshness of cooked rice, which greatly affects palatability and acceptability of consumers [2,3]. The extraction and analysis of volatile organic compounds (VOCs) in packaged cooked rice by the gas chromatographic technique demonstrated that the concentration of geranyl acetone (*X*) decreased with prolongation of storage time, which was mainly caused by the oxidation of compounds due to residual oxygen in the package [4]. However, even though geranyl acetone is a common biomarker of diverse cooked rice, fruits, and plant diseases [5,6], there were few research methods on gas sensing properties for monitoring it, and the demands for accurate evaluation and nondestructive testing of early cooked rice spoilage at ppb level are tough to approach as well [7].

A semiconductor metal oxide (SMOX) gas sensor with characteristics of low loss, non-toxicity, real-time detection, and ease of production can effectively detect VOCs with low concentrations under different circumstances [8–10]. Tungsten trioxide (WO$_3$) is a significant SMOX material with an appropriate bandgap, high oxygen vacancies (O$_V$), and excellent

electron transfer properties displaying highly stable, classical transition feature, different crystalline nanostructure, and high sensitivity [11–14], which has been widely used for VOC detection (Table S1 in the Electronic Supplementary Material (ESM)). However, WO_3 gas sensors have been facing challenges in practical applications on account of poor selectivity and required high operating temperatures. Therefore, abundant researchers devoted to the manufacture of cryogenic sensors [15], and relevant research has been in-depth developed to modify physicochemical nature of pristine WO_3 for solving the existing bottleneck. Among noble-metal sensitization [16], morphological control [17], metallic impurity doping [18], heterostructure construction [12], and other referential methods, doping metallic impurities is deemed as a feasible means to enhance gas sensing features [19]. Specifically, doping with Fe^{3+} in SMOX can boost the optical band-gap width and conductivity, meanwhile modifying electronic structures and surface chemical states of materials [20], thereby strengthening VOC sensing applications of SMOX [21].

In this context, we reported the WO_3 nanoparticles doped with certain amounts of iron (Fe) ions (0%, 2%, 3%, 4%, and 5%) contributing to ultrasensitive sensing performance by combing the properties of low limit of detection (LOD) (237 ppb), excellent sensitivity (~23.47), fast response (~41 s), and favorable long-term stability for 6 ppm geranyl acetone at room temperature. The density functional theory (DFT) and valence band X-ray photoelectron spectroscopy (VB-XPS) analysis were carried out for elaborating on the sensing enhancement mechanism. In addition, the practicality was verified by studying early spoilage conditions of cooked rice by the as-prepared optimal sensors. The investigation and acquired findings put forward a novel candidate for monitoring characterized VOCs generated from cooked rice under different conditions, which probably ameliorates rice cooking methods, affects packaged cooked rice industry positively, and improves palatability for consumers.

2 Materials and methods

All the chemicals utilized in experiments pertained to the analytical grade and were directly utilized without any purification. Sodium tungstate dihydrate ($Na_2WO_4 \cdot 2H_2O$) ($\geq 99.5\%$) and HNO_3 (65–68 wt%) were purchased from Sinopharm Chemical Reagent

Co., Ltd. Anhydrous ferric chloride ($FeCl_3$) ($\geq 98\%$) was obtained from Anhui Senrise Technology Co., Ltd. Anhydrous ethanol was acquired from Chinasun Specialty Products Co., Ltd.

2. 1 Synthesis of Fe-doped WO_{3-x} nanoparticles

Pristine WO_3 and Fe-doped WO_{3-x} nanoparticles were obtained through a facile one-step solvothermal reaction (Fig. S1 in the ESM). In a concrete process, 2 mmol $Na_2WO_4 \cdot 2H_2O$ was dissolved and dispersed in a commixture of 20 mL deionized water and 30 mL HNO_3 (65 wt%) followed by stirring vigorously for 20 min. The final solution was moved into a Teflon-lined stainless autoclave (100 mL) and subsequently kept at 160 ℃ for 10 h. After cooling down to ambient temperature, the precipitates were washed with deionized water and absolute alcohol alternatively, and finally dried at 60 ℃ for 16 h. For improving crystallinity of WO_3, the obtained powders were calcined at 550 ℃ for 3 h at a ramp rate of 2 ℃·min^{-1}. As for Fe–WO_{3-x} samples, the preparation procedure is the same except that $FeCl_3$ of different amounts are added in the first step of the synthesis. The samples prepared by adding 0, 0.0054, 0.0081, 0.0108, and 0.0135 g of $FeCl_3$ were nominated as WO_3, 2% Fe–WO_{3-x}, 3% Fe–WO_{3-x}, 4% Fe–WO_{3-x}, and 5% Fe–WO_{3-x}, respectively, which are based on the molar ratios of Fe^{3+} to W^{6+}. All samples presented a flaxen color as abundant O_V.

2. 2 Material characterization

Phase identification and crystal forms of the samples were gained by an X-ray diffractometer (D8 Advance, Bruker), and the micromorphology analysis was obtained by a field emission-scanning electron microscope (FE-SEM; S4800, Hitachi), a transmission electron microscope (TEM; G2 F30 S-TWIN, Tecnai), and an atomic force microscope (AFM; SPM-9700HT, Shimadzu). Ultraviolet–visible (UV–Vis) absorption spectra and bandgap were obtained via an ultraviolet–visible–near infrared (UV–Vis–NIR) spectrophotometer (Cary 5000, Varian). Chemical states of relevant elements and their distribution uniformity were observed via an X-ray photoelectron spectrometer (ESCALAB 250Xi, Thermo Scientific) and a high-angle annular dark-field scanning transmission electron microscope (HAADF-STEM) combined with an energy dispersive spectrometer, respectively. The X-ray photoelectron spectrometer

was calibrated with binding energy of the C 1s peak (284.8 eV). The surface O_V was confirmed through an electron paramagnetic resonance (EPR) spectrometer (A300-10/12, Bruker), while rotational and vibrational modes and photoluminescence (PL) spectroscopy were analyzed by Raman spectrometer (Renishaw inVia). Brunauer–Emmett–Teller (BET) surface area with N_2 adsorption/desorption isotherms and pore-size distribution was investigated via a specific surface and aperture analyzer (Autosorb IQ3, Quantachrome Instruments).

2. 3   Gas sensing setup and sensor characterization

All sensors were fabricated by mixing the powders with deionized water, and then ground to generate uniform pastes. The surfaces of the electrode were dip-coated by the homogenous pastes, and then dried at 130 ℃ for 24 h and further aged in a muffle furnace (KSL-1200X, HF-Kejing) at 200 ℃ for 72 h for thermal stabilization, avoiding the sensor signal drift. The experimental facilities employed in this investigation were the same as those reported in Refs. [22,23]. The real-time electrical resistance was presented via a gas tester (SD 101, Wuhan Huachuang Ruike Technology Co., Ltd.). The response of the gas sensor (*S*) utilized in this work is defined by Eq. (1):

$$S = R_a /R_g \tag{1}$$

where R_a and R_g represent the resistance of the gas sensor after exposure to pure air (79% N_2 + 21% O_2) and geranyl acetone, respectively. Additionally, the response/recovery time (τ_{res}/τ_{rec}) was obtained according to the duration reaching 90% of the resistance variation of the fabricated sensor during the adsorption and desorption of geranyl acetone molecules, respectively.

In the experiments, the flow rate of the vapor and the static and dynamic test conditions need to be accurately controlled, as the sensor response will be affected by the heat exchange process between itself and surrounding vapor [24]. More details for the gas sensing setup and practicability applications are provided in Section S2 in the ESM.

3   Results and discussion

3. 1   Characterization results

Crystal phase compositions and fineness of the as-synthesized materials were investigated via X-ray diffraction (XRD). As shown in Fig. 1(a), all diffraction peaks of the as-prepared samples were well indexed to the standard card of monoclinic phase WO_3 (space group: *P*21/*a*, JCPDS No. 05-0363), while the peaks of monoclinic WO_3 appear at 23.175°, 23.631°, 24.421°, 26.652°, 29.005°, 33.357°, 34.236°, and 42.010° corresponding to the (001), (020), (200), (120), (111), (021), (220), and (221) planes, respectively. Moreover, the *d*-spacing values and crystallite sizes (*D*) of the as-prepared samples can be obtained by Bragg equation [22] (Eq. (2)) and Scherrer equation [25] (Eq. (3)), respectively, as listed in Table 1, while the full width at half maximum (FWHM) and peak positions of the following XRD patterns were calculated by a multi-peak fitting using Gaussian algorithm.

$$2d_{hkl}\sin\theta = n\lambda \tag{2}$$
$$D = \frac{k\lambda}{\beta\cos\theta} \tag{3}$$

Fig. 1   (a) XRD patterns of WO_3, 2% Fe–WO_{3-x}, 3% Fe–WO_{3-x}, 4% Fe–WO_{3-x}, and 5% Fe–WO_{3-x}; (b) texture coefficient ($TC_{(hkl)}$) values of all samples.

Table 1   Structural parameters of as-prepared samples

Sample	Cell parameter (Å)			Cell volume (Å³)	D (nm)
	a	b	c		
WO_3	7.287	7.517	3.836	210.122	23.90
2% Fe–WO_{3-x}	7.285	7.516	3.834	209.927	24.43
3% Fe–WO_{3-x}	7.283	7.514	3.831	209.649	19.45
4% Fe–WO_{3-x}	7.282	7.511	3.829	209.428	20.10
5% Fe–WO_{3-x}	7.280	7.509	3.826	209.150	24.39

where θ refers to the Bragg angle, β represents the FWHM (in rad), k (= 0.94) refers to the shape factor, and λ (= 0.15406 nm) refers to the wavelength of X-ray source. n represents the diffraction order (for the first order, $n = 1$), while d_{hkl} is the interplanar spacing (in Å). Specifically, no characteristic peaks arising from Fe metal are detected in Fe-doped WO_{3-x}, indicating that the Fe content of doping is too low, or Fe ions are embedded into the crystal lattice of WO_3. Then, the valence states of the embedded Fe ions were further verified. As the ionic radii of W^{6+}, Fe^{3+}, and Fe^{2+} are 0.0600, 0.0550, and 0.0630 nm, respectively [26,27], the replacement of W^{6+} ions in WO_3 with larger metal ions will contribute to the enlargement of a crystal cell [28]. As the synthesized Fe-doped WO_{3-x} belongs to the monoclinic crystal system, the lattice constants (a, b, and c) can be obtained by Eq. (4), as listed in Table 1.

$$\frac{1}{d_{hkl}^2} = \frac{\frac{h^2}{a^2}+\frac{k^2}{b^2}+\frac{l^2\sin^2\gamma}{c^2}-\frac{2hk\cos\gamma}{ab}}{1-\cos^2\gamma}$$
$$= \frac{h^2}{a^2\sin^2\gamma}+\frac{k^2}{b^2\sin^2\gamma}+\frac{l^2}{c^2}-\frac{2hk\cos\gamma}{ab\sin^2\gamma}\gamma \quad (4)$$

where h, k, and l refer to the crystal face index, and γ is an angle in the lattice constant. Notably, the lattice parameters and cell volumes of the samples reduced gradually with the rising concentration of the Fe dopant, illustrating that Fe^{3+} was successfully doped into the lattice of WO_3.

Furthermore, the $TC_{(hkl)}$ parameters are obtained by Eq. (5) for further explanation [29,30]:

$$TC_{(hkl)} = \frac{I_{(hkl)}/I_{0(hkl)}}{\frac{1}{N}\sum I_{(hkl)}/I_{0(hkl)}} \quad (5)$$

where $I_{(hkl)}$ and $I_{0(hkl)}$ refer to the relative and standard peak intensities in XRD patterns, respectively, and N refers to the reflection number. The calculated TC values and their corresponding variations are shown in

Table S2 in the ESM and Fig. 1(b), respectively. Different amounts of doping may cause re-orientation effect, manifesting that the (200), (111), and (220) planes got preferential growth, as shown in Fig. 1(b). The TC values of the (200), (111), and (220) planes reached the maximum values of 1.1708, 0.9733, and 1.2318 in 3% Fe–WO_{3-x}, respectively, while the increasing amounts of Fe doping caused a transformation in the preferred orientation to the (021) plane in the 5% Fe–WO_{3-x} sample. In detail, the surface energy sequence of monoclinic WO_3 is (020) < (200) < (220). Consequently, taking advantage of changing Fe doping contents makes specific exposed facets possess higher surface energy, enhancing physical–chemical activity of sensing materials [31].

Morphologies and microstructures of WO_3 and Fe-doped WO_{3-x} were inspected via FE-SEM and high-resolution TEM (HRTEM), respectively. As shown in Fig. 2(a) and Fig. S3 in the ESM, all samples own the nanoparticle-like morphology, while the lengths of the nanoparticles are around 50–150 nm. The average particle size of 3% Fe–WO_{3-x} is around 110 nm, as shown in Fig. S4 in the ESM, and all Fe-doped WO_{3-x} nanoparticle-liked samples distinctly displayed flat and smooth features with wrinkling. AFM images with a non-contact mode are taken in Fig. S5 in the ESM. As the thicknesses of WO_3 and 3% Fe–WO_{3-x} are both ~25 nm, the doping of Fe^{3+} represents no apparent impact on the microstructure of different samples. From the HRTEM results (Figs. 2(b)–2(e)), nanoparticle-like 3% Fe–WO_{3-x} was displayed, and the HRTEM images along with a homologous selected area electron diffraction (SAED) pattern, which is shown in Fig. 2(f), were obtained from a random optional field. The diffraction ring of the SAED pattern does not exist, which indicated the single crystal property of Fe-doped WO_{3-x} nanoparticles [32]. In addition, the contrast of Fe vs. W cations can be seen in intensity profiles (Fig. S6 in the ESM) obtained from the marked area "1" of 3% Fe–WO_{3-x}, which indicated good doping of the Fe ions [33]. Energy dispersive spectroscopy (EDS) elemental mappings (Figs. 2(g)–2(i)) demonstrate the presence of W, O, and fewer Fe, which were homogeneously distributed among the nanoparticles.

Raman spectra were depicted for acquiring molecular structures and compositions of all samples. Two Raman peaks centered at 680 and 803 cm^{-1} were attributed to the O–W–O modes, while the peak around
Fig. 2 (a, b) FE-SEM images of 3% Fe–WO$_{3-x}$; (c, d) HRTEM images of 3% Fe–WO$_{3-x}$; (e) lattice distances of various crystal planes of 3% Fe–WO$_{3-x}$; (f) SAED pattern of 3% Fe–WO$_{3-x}$; (g–i) STEM–EDS mappings of O, W, and Fe of 3% Fe–WO$_{3-x}$.

267 cm^{-1} may assign to bending vibration of δ(O–W–O), which is shown in Fig. 3(a) [34]. As a result, the crystal structures of the samples may comprise a network within homocentric WO$_6$ octahedron elements, which constitute O–W–O microcrystalline clusters that are interconnected by W–O–W, with the terminal W=O bonds at the surface of the clusters [35]. As evident in Fig. 3(b), adsorption–desorption isotherms of 3% Fe–WO$_{3-x}$ are attributed to type-IV isotherms according to International Union of Pure and Applied Chemistry (IUPAC) classification, and the specific surface area of 3% Fe–WO$_{3-x}$ is up to 25.729 m$^2\cdot$g^{-1}, contributing to providing rich oxygen adsorption sites and further facilitating carrier transportation. Pore-size distribution curves (Fig. 3(c)) demonstrate that 3% Fe–WO$_{3-x}$ was assigned to mesoporous materials with an average pore diameter of 3.139 nm. Furthermore, other BET test results of the as-synthesized samples are listed in Table S3 in the ESM.

Optical bandgaps of all samples were analyzed by the UV–Vis testing. Specifically, the light absorption

edge wavelengths of five samples are in the range of approximately 502.87–514.23 nm, as shown in the inset of Fig. 3(d). The E_g values are calculated by Kubelka–Munk equation (Eq. (6)) [36] and demonstrated in Fig. 3(d). 3% Fe–WO$_{3-x}$ owns the narrowest bandgap of 2.42 eV, which will accelerate the electron transition speed, thereby enhancing the sensing performance.

$$\alpha h v = A(h v - E_g)^{m/2} \tag{6}$$

where A is an integer, and the value of m for WO$_3$ is 1 due to its direct optical transition type. The elemental composition was evaluated via XPS. All the Fe–WO$_{3-x}$ samples contained the corresponding elements including Fe, W, and O (Fig. 4(a)). The chemical states of the Fe ions in the 3% Fe–WO$_{3-x}$ nanoparticles are explored in Fig. 4(b). The characteristic peaks at 724.38 and 710.22 eV indexed well to Fe 2p$_{1/2}$ and Fe 2p$_{3/2}$, respectively, while satellite peaks at ca. 732.46 and 718.40 eV were corresponding to the Fe^{3+} species [37]. Furthermore, the O 1s peaks (Fig. 4(c)) can generally be divided into three kinds of oxygen species for both
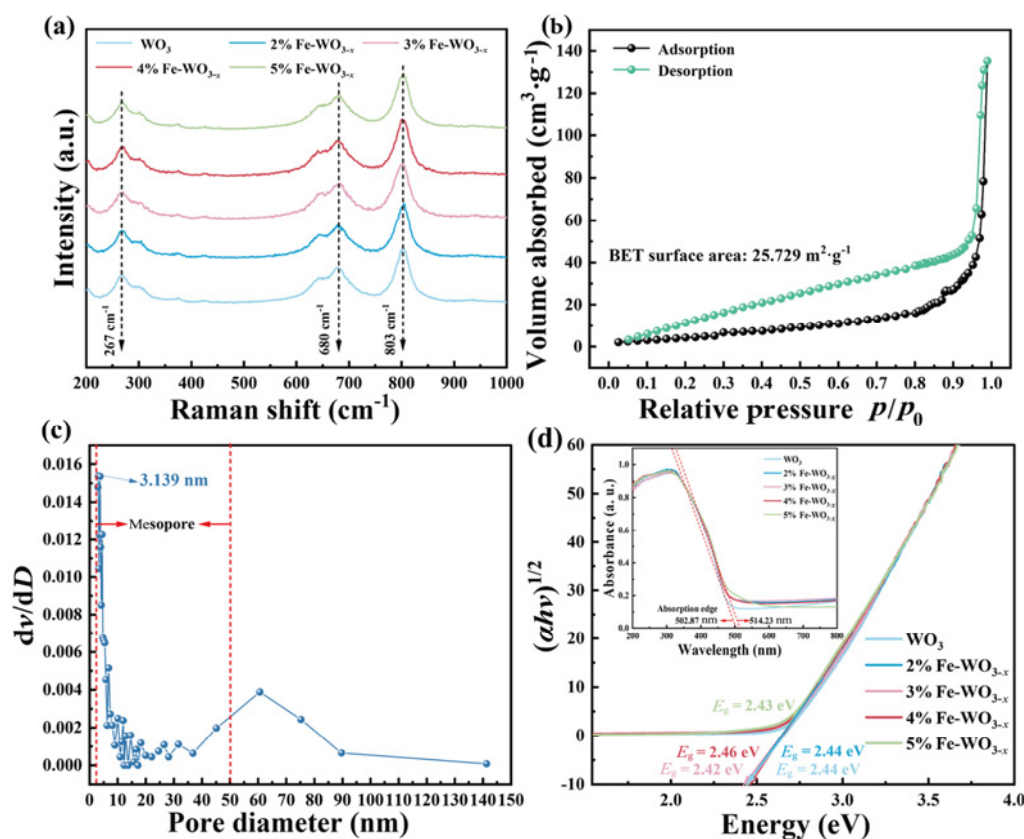

Fig. 3 (a) Raman spectra of all samples; (b) N_2 adsorption–desorption isotherms of 3% Fe–WO_{3-x} where p is the true pressure of the gas, and p_0 is the saturated vapor pressure of the gas at the measured temperature; (c) pore-size distribution of 3% Fe–WO_{3-x}; (d) calculated band-gap energies (E_g) of all samples (the inset is the UV–Vis diffuse absorbance spectra of all samples).

pure WO_3 and 3% Fe–WO_{3-x}, which are the lattice oxygen (O_L), O_V, and chemisorbed oxygen (O_C). In detail, O_L, O_V, and O_C of WO_3 and 3% Fe–WO_{3-x} are 530.28, 530.78, and 531.86 eV and 529.96, 530.39, and 531.44 eV, respectively. The proportions of O_V and O_C in 3% Fe–WO_{3-x} were higher than those of pristine WO_3, which enhanced the gas sensing performance for that O_V motivated numerous active gas adsorption sites and accelerated the reaction between the target VOC molecule and the surface of the sensing materials, while O_C primarily participated in the surface redox reaction of the VOC molecules onto the SMOX materials [38]. As shown in Fig. 4(d), W 4f can be divided into two specific peaks located at 37.75 and 35.60 eV assigned to W $4f_{5/2}$ and W $4f_{7/2}$, respectively. As for 3% Fe–WO_{3-x}, the declined binding energy of W 4f (37.46 and 35.30 eV for W $4f_{5/2}$ and W $4f_{7/2}$, respectively) revealed that the incorporation of the Fe^{3+} ions in the crystalline structure of the samples replaced W^{6+} ions, in line with the XRD results [39]. These results indicated that the Fe ions consist in the WO_3 nanoparticles via a fast and facile method, and Fe-

doped WO_{3-x} may enhance the gas sensing performance under real testing conditions.

As illustrated in Fig. 4(e), the PL spectra indicated that the addition of the Fe contents increased the concentration of O_V. Furthermore, EPR signals of five samples display one peak consistent with a *g* factor (the *g* value represents the factor of a free radical or unpaired electron in the EPR spectrum) of 2.003, as shown in Fig. 4(f). The results further demonstrate that there existing larger number of O_V in 3% Fe–WO_{3-x} samples, which is believed that the enhancement of the signal was derived from the production of W^{5+} [40]. Specifically, O_V can localize electrons, which will transfer to W^{6+}, leading to the generation of W^{5+} [41].

3. 2　Gas sensing performance

The sensing performance of pristine WO_3 and Fe–WO_{3-x} nanoparticles was investigated under room-temperature conditions (25±2 ℃). First of all, the 3% Fe–WO_{3-x} gas sensor was tested by exposing them to 8 ppm geranyl acetone at different working temperatures. The response declined as the working
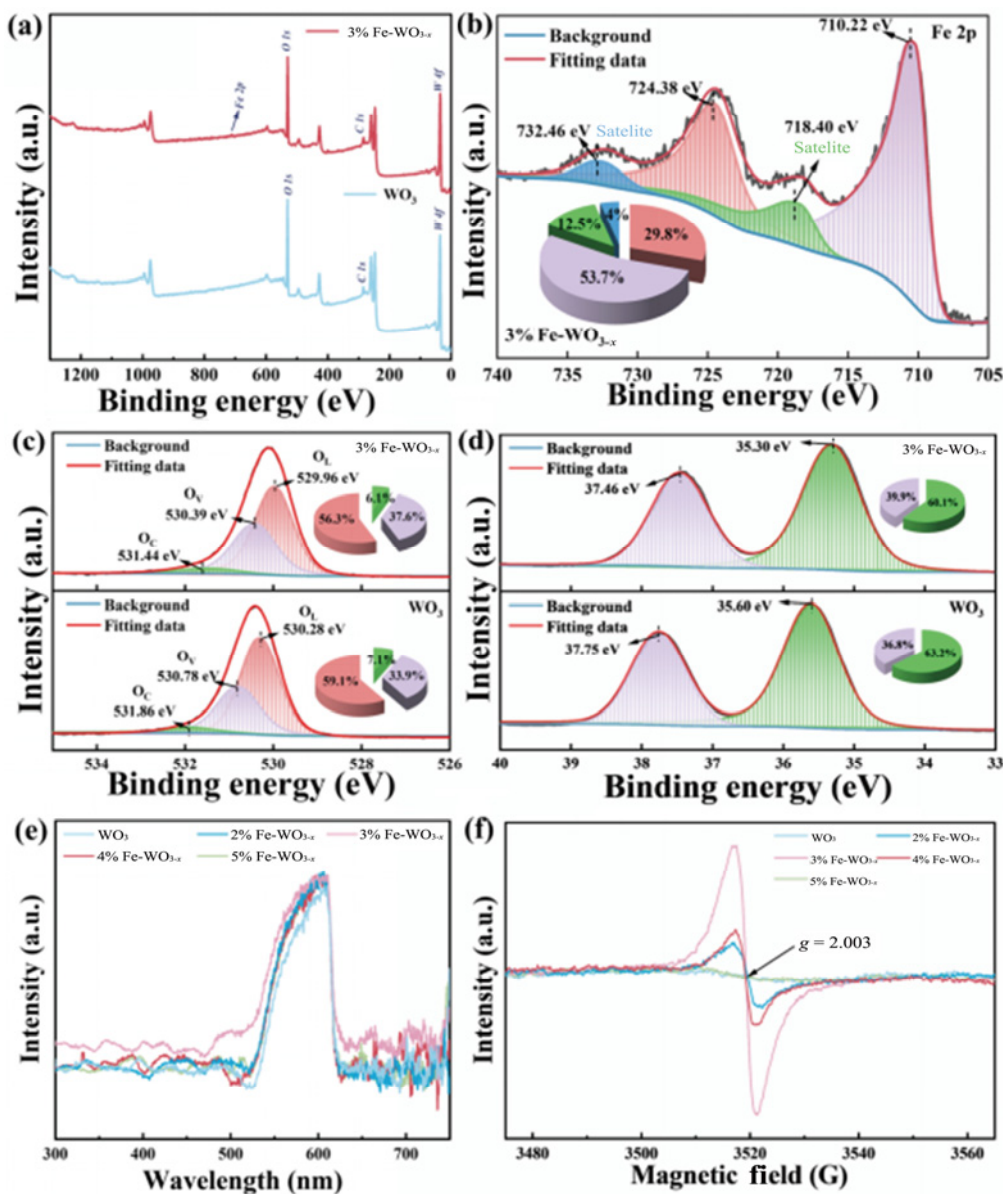

Fig. 4 Element chemical states of pristine WO₃ and 3% Fe–WO$_{3-x}$ composite determined by XPS: (a) survey spectra; (b) Fe 2p spectra; (c) O 1s spectra; (d) W 4f spectra. (e) PL spectra and (f) EPR measurement at room temperature of all samples.

temperature increased between room temperature and 100 ℃ (Fig. S7 in the ESM), suggesting that room temperature is the optimal selection for gas sensing. Figures 5(a) and 5(b) and Fig. S8 in the ESM depict the transient gas sensing characteristic of the as-fabricated gas sensors at diverse concentrations of geranyl acetone ranging from 2 to 10 ppm. Above all, the transient response–recovery behavior reveals reversible and relatively stable sensing properties of Fe-doped WO$_{3-x}$ onto geranyl acetone, and the 3% Fe–WO$_{3-x}$ sensor owns the greatest response values (2.42, 10.65, 23.47, 41.32, and 82.7 at 2, 4, 6, 8, and 10 ppm geranyl acetone, respectively) compared

with those of other gas sensors made in the same batch. Furthermore, the response values of all gas sensors came up equally when X is increased, which are listed in Table S7 in the ESM. The relationship of 3% Fe–WO$_{3-x}$ gas sensor response values (Y) vs. X (Fig. 5(c)) abides by a stepwise distribution, and it can be fitted by the typical parabola relation:

$$Y = AX^2 + BX + C \qquad (7)$$

where A represents the quadratic term coefficient, B represents the first-order coefficient, and C represents a constant term. On the fundament of the parabola law, A, B, and C are 1.281, −5.975, and 12.088, respectively. For evaluating the reproducibility of the gas sensors,

Fig. 5(d) illustrates 5 cycles of the 3% Fe–WO$_{3-x}$ gas sensor towards 6 ppm geranyl acetone, while the response values maintained around 24.5, and the corresponding standard deviation is 0.54. As shown in Figs. 5(e) and 5(f), the transient response curves of 3% Fe–WO$_{3-x}$ and pure WO$_3$ exhibit τ_{res}/τ_{rec} of 41 s/480 s and 56 s/383 s, respectively. The long-term stability was tested by inletting 6 ppm geranyl acetone to 2% Fe–WO$_{3-x}$ and 3% Fe–WO$_{3-x}$ sensors for one month. As shown in Fig. 5(g), the error bar with a fill area of response stable characteristic illustrated that there was almost no variation in the response value within one month. Furthermore, the cross selectivity has always been vulnerability that is difficult to

overcome due to the inherent sensing principle of the SMOX gas sensors. Thus, we explored the selectivity by calculating the selectivity coefficient (K), as shown in Fig. 5(h), and the gas concentration was kept at 10 ppm, while the equation is shown by Eq. (8) [42]:

$$K = \frac{S_{\text{target gas}}}{S_{\text{interference gas}}} \tag{8}$$

where $S_{\text{target gas}}$ and $S_{\text{interference gas}}$ are the response of the target gas and the interference gas, respectively.

For the WO$_3$ gas sensor, K was calculated to be 2.80, 3.59, 3.97, 5.01, 5.48, 5.75, and 6.76 for nonanal, 1-octen-3-ol, 2-pentylfuran, ethanol, hexanal, linalool, and pyridine, respectively, while the corresponding

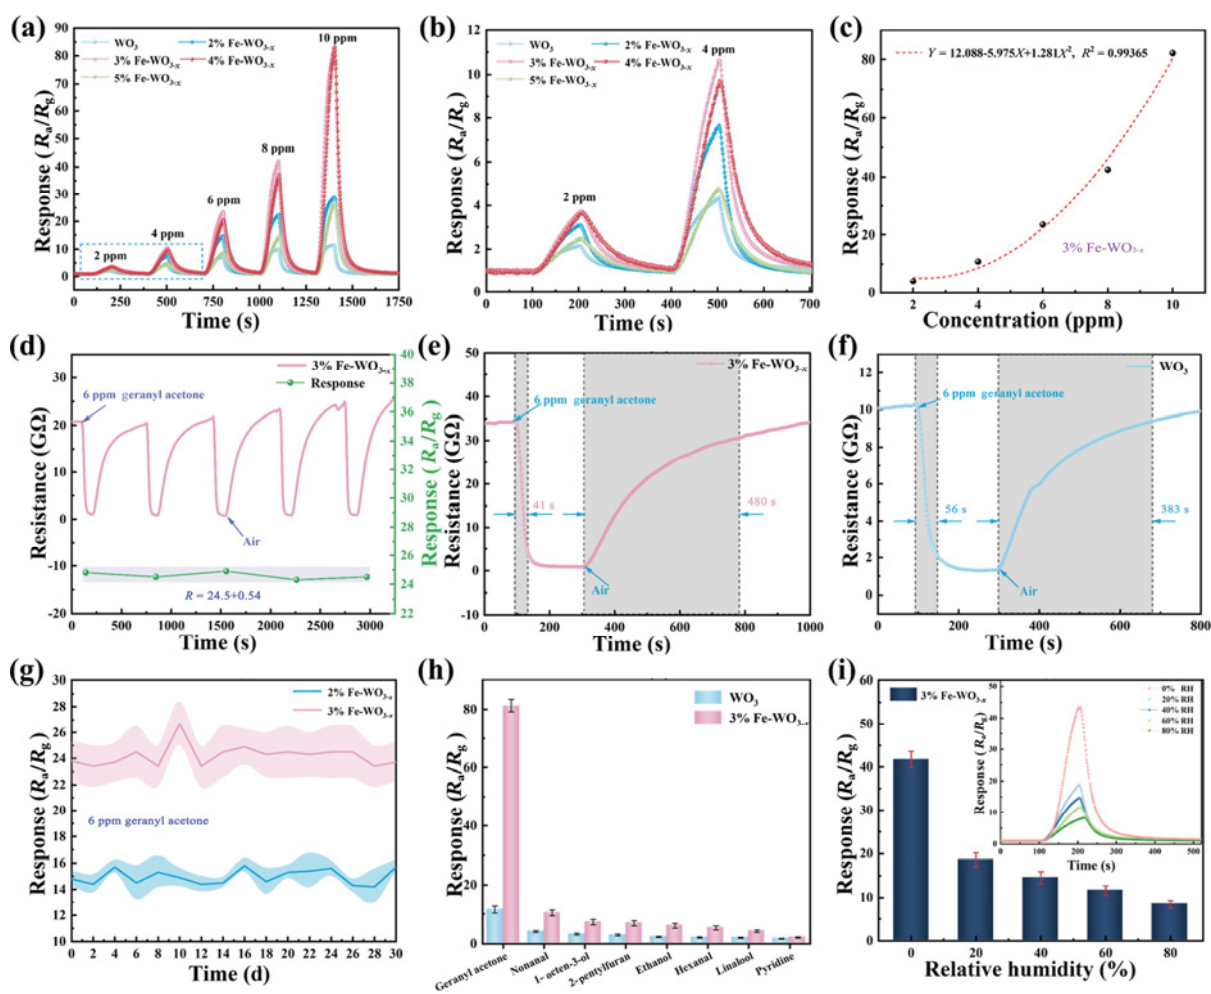

Fig. 5 (a) Dynamic response/recovery curves of five samples to 2–10 ppm geranyl acetone at room temperature; (b) dynamic response/recovery curves of five samples to 2–4 ppm geranyl acetone at room temperature; (c) relationship of Y vs. X where R^2 is the coefficient of determination to evaluate the goodness of fit of the regression model coefficients; (d) response to 6 ppm geranyl acetone of 3% Fe–WO$_{3-x}$ in 5 cycles; (e) τ_{res}/τ_{rec} of 3% Fe–WO$_{3-x}$ to 6 ppm geranyl acetone at room temperature; (f) τ_{res}/τ_{rec} of WO$_3$ to 6 ppm geranyl acetone at room temperature; (g) error bars with fill area of response stable characteristic of 2% Fe–WO$_{3-x}$ and 3% Fe–WO$_{3-x}$ sensor to 6 ppm geranyl acetone in one month; (h) selectivity to 10 ppm geranyl acetone and various gases of WO$_3$ and 3% Fe–WO$_{3-x}$ at room temperature (error bar (o) = 3); (i) variation of response values and baseline resistance vs. relative humidity (RH) of 3% Fe–WO$_{3-x}$ (error bar (o) = 3) (the inset is corresponding response/recovery curves 3% Fe–WO$_{3-x}$ to 8 ppm geranyl acetone under different RHs).
results are 7.82, 11.14, 11.78, 13.33, 15.34, 19.36, and 38.71, respectively, for the 3% Fe–WO$_{3-x}$ gas sensor. The data acquired from the 3% Fe–WO$_{3-x}$ gas sensor processed outstanding selectivity towards 10 ppm geranyl acetone at room temperature.

In a real test environment, RH can vary from 5% to 95% with accuracy of ±2.5% [43], and thus the response values of the 3% Fe–WO$_{3-x}$ gas sensor under different RHs are shown in Fig. 5(i). When RH increased from 20% to 80%, the sensitivity decreased due to adsorbed water molecules, restricting the efficient adsorption of oxygen and geranyl acetone molecules. Above all, the reduced adsorbed geranyl acetone molecules bring about a declining response in higher humidity.

In detection circumstances of real cooked rice flavor, X is as low as ppm or ppb level, and thus LOD of the as-prepared gas sensor should be probed [22]. The details about the LOD calculation are given in Section S3 in the ESM. Thus, LODs of WO$_3$ and 3% Fe–WO$_{3-x}$ were 431 and 237 ppb respectively, which revealed the excellent practical application of the room-temperature geranyl acetone sensor.

3. 3   Gas sensing mechanism

An intuitive scheme for sensing enhancement mechanism of the WO$_3$ sensor for geranyl acetone vapor is provided in Fig. 6(a). Once sensors expose themselves to high-purity air, some oxygen molecules will be absorbed by the sensing materials chemically, while the electrons located at the conduction band (CB) were retrieved to form O$_2^-$ at room temperature (Reactions (9) and (10), respectively). Therefore, the electron depletion layer becomes thinner, and the bending of the energy band can be illustrated by the rising of the sensing material resistance. After injecting the target VOC (geranyl acetone) into a gas chamber, the geranyl acetone molecule combined with oxygen species to generate the electrons, which will return to CB (Reaction (11)), narrowing the electron depletion layer and further increasing the conductivity of the materials [44,45]. Therefore, the variation of the gas sensor resistance proved that the as-fabricated gas sensors are appropriate for detecting low concentrations of geranyl acetone.

$$O_2(gas) \leftrightarrow O_2(ads) \qquad (9)$$

$$O_2(ads)+e^- \leftrightarrow O_2^-(ads) \ (temperature < 150\ ℃) \quad (10)$$

$$C_{13}H_{22}O(gas)+18O_2^- \rightarrow 13CO_2(gas)+11H_2O+18e^- \quad (11)$$

As Fe^{3+} replaces W^{6+}, some O$_V$ are induced accompanied by the Fe doping based on the defect model using Kröger–Vink reaction (Reaction (12)). Specifically, O$_V$ are ulteriorly ionized into second-order-ionized O$_V$ (V$_{\ddot{O}}$), and adsorbed oxygen will capture more free electrons by intensifying the surface redox reaction of VOC molecules onto the sensing materials and further improving the gas sensor performance (Reaction (13)) [46].

$$WO_3 \rightarrow W_{Fe}+O_O \qquad (12)$$

$$O_O \rightarrow V_{\ddot{O}}+1/2O_2+2e^- \qquad (13)$$
where O$_O$ is the specific concentration of the oxygen vacancy which is induced by Fe-doping. To further explore the enhanced sensing mechanism, the CB potential of the samples (E_{CB}) is calculated below, and the VB potential can be obtained via the VB-XPS technique ($E_{VB,XPS}$, Figs. 6(b)–6(d)). Therefore, $E_{VB,XPS}$ of WO$_3$ and 3% Fe–WO$_{3-x}$ are 2.22 and 1.84 eV, respectively.

$$E_{VB,NHE} = \varphi + E_{VB,XPS} - 4.44 \qquad (14)$$

where φ (= 4.52 eV) represents the work function of the XPS tester. Therefore, the VB potential obtained by the normal hydrogen electrode ($E_{VB,NHE}$) of WO$_3$ and 3% Fe–WO$_{3-x}$ are calculated to be 2.30 and 1.92 eV, respectively (Eq. (14)). Furthermore, the relationship between the work function in Φ and ΔV is shown in Eq. (15) [47]:

$$\Delta V = \Phi - \varphi \qquad (15)$$

where ΔV refers to the distance between adjacent IPs (Figs. 6(c) and 6(d)). Thus, Φ of WO$_3$ and 3% Fe–WO$_{3-x}$ are 5.82 and 6.60 eV, respectively, and then the band structures can be obtained (Fig. 6(e)). Combined with all characterization assays and gas sensitivity tests, by adjusting the Fe doping content during the preparation of WO$_3$, O$_V$ is regulated, and the band structure of metal oxide materials is changed. Comparing 3% Fe–WO$_{3-x}$ with WO$_3$, as the concentration of O$_V$ increases, the resulting free electrons will generate a new donor energy level in the forbidden band. Then hybridization occurs when the new donor level is in contact with VB, and the top of VB expands and shifts upward, thereby narrowing the bandgap [48].

Furthermore, the increase of the solvothermal temperature magnifies the Fermi level by 0.78 eV, indicating the improvement of charge carrier compensation from the establishment of the nanosheet
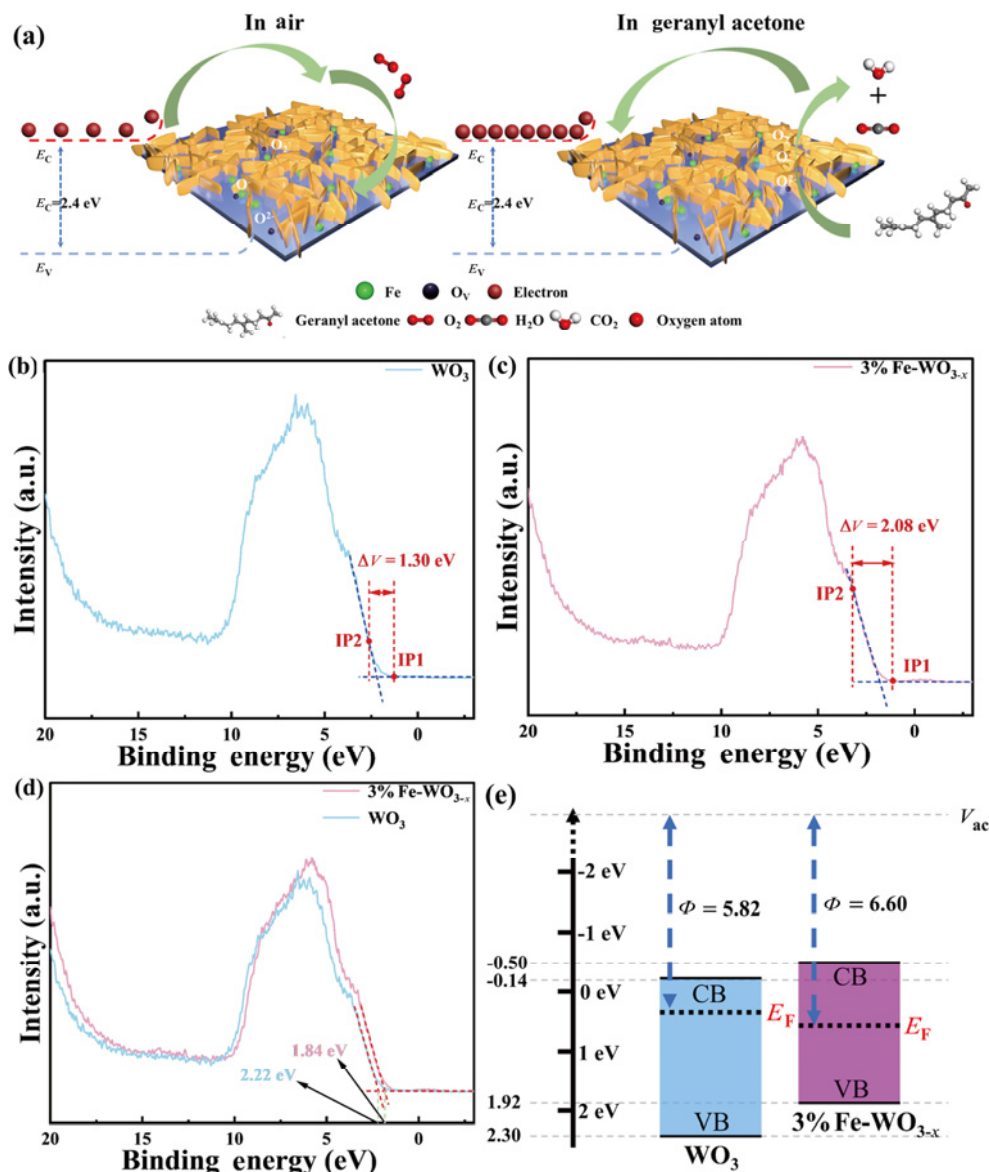

Fig. 6 (a) Schematic illustration of gas sensing mechanism for Fe-doped WO_{3-x}; work functions of (b) WO_3 and (c) 3% Fe–WO_{3-x}; (d) VB-XPS spectra of WO_3 and 3% Fe–WO_{3-x}; (e) band structures of WO_3 and 3% Fe–WO_{3-x}. Note: E_C and E_V are the energy of CB and VB, respectively, IP is the abbreviation of inflection point, ΔV is the contact potential difference, V_{ac} is the vacuum level which is defined as the energy level at which electrons are not attracted to nucleus and become free electrons, E_F is the energy of Fermi level, and Φ is the actual VOC detection.

heterojunction, which results in better geranyl acetone sensing performance.

To further explore the gas sensing mechanism for geranyl acetone to WO_3 and Fe–WO_{3-x}, the adsorption reaction between the geranyl acetone molecules and the surface of the as-prepared materials was simulated through Cambridge Sequential Total Energy Package (CASTEP) modules, and other setting details of the DFT calculation are given in Section S4 in the ESM. After surface cleaving of optimal WO_3 and Fe–WO_{3-x} crystals, the adsorption energy of the geranyl acetone

molecules on WO_3 (011) and Fe–WO_{3-x} (011) (E_{ads}) can be calculated by Eq. (16):

$$E_{ads} = E_{total} - (E_{(011)} + E_{geranyl\ acetone}) \qquad (16)$$

where E_{total} refers to the total energy of the geranyl acetone molecules absorbed on the certain crystal facet of the WO_3 and Fe–WO_{3-x} surface systems, $E_{(011)}$ is the energy towards (011) WO_3 and Fe–WO_{3-x} surface, and $E_{geranyl\ acetone}$ refers to the energy of the isolated geranyl acetone molecules.

As evident in Figs. 7(a) and 7(b), the calculated E_g

values of WO_3 and $Fe–WO_{3-x}$ are 1.52 and 1.15 eV, respectively, indicating the formation of a narrower bandgap after the Fe doping, resulting from that the relatively bigger change of the bandgap was displayed for the higher doping contents setting in simulation. Figures 8(c) and 8(d) are the optimized primitive crystal structures of WO_3 and $Fe–WO_{3-x}$, respectively. Furthermore, the density of states (DOSs) of WO_3 and $Fe–WO_{3-x}$ are depicted in Figs. 7(c) and 7(d), respectively, which indicate that the VB maximums

(VBMs) of WO_3 and $Fe–WO_{3-x}$ are primarily comprised of the O 2p orbital, and the CB minimums (CBM) of WO_3 and $Fe–WO_{3-x}$ are the constitutions of hybrid orbitals within W 5d and O 2p and W 5d, O 2p, and Fe 3d, respectively. The DOS results demonstrate that the electrons may originate from the O 2p orbitals of WO_3 and $Fe–WO_{3-x}$, and then can be further excited about the hybrid orbitals of W 5d, O 2p, and Fe 3d [49].

To obtain the adsorption energy, the geometry structures for geranyl acetone adsorption systems of

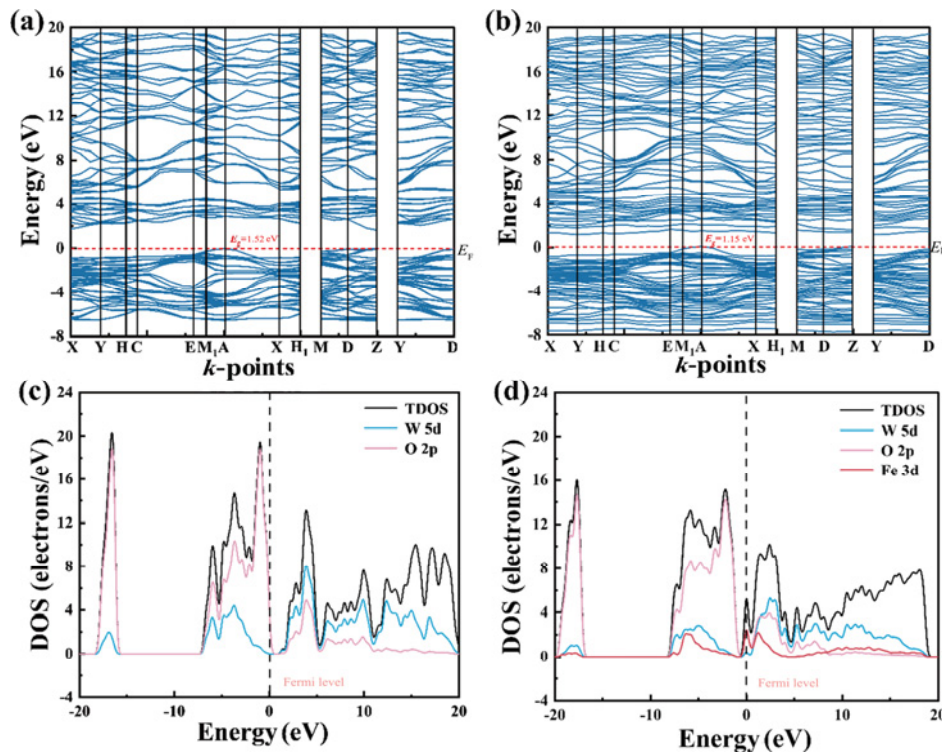

Fig. 7 Band structures of (a) WO_3 and (b) $Fe–WO_{3-x}$ in monoclinic (MCL) lattice; DOSs of (c) WO_3 and (d) Fe-doped WO_{3-x} where TDOS is the abbreviation of total density of states.

Fig. 8 Geometry structures for geranyl acetone adsorption systems of (a) WO_3 and (b) Fe-doped WO_{3-x}; geometry structures for (c) WO_3 and (d) Fe-doped WO_{3-x}; schematic diagrams of differential charge densities in geranyl acetone adsorption processes of (e) WO_3 and (f) Fe-doped WO_{3-x}.

WO$_3$ and Fe–WO$_{3-x}$ are built in Figs. 8(a) and 8(b), respectively. The distances between geranyl acetone and WO$_3$ and Fe–WO$_{3-x}$ matrices are 2.572 and 2.736 Å, respectively, while the corresponding adsorption energy is −0.95 and −1.23 eV, respectively, and the specific parameters of the two adsorption systems are listed in Table S10 in the ESM. The adsorption energy indicates the strongest binding of the geranyl acetone molecule to the Fe–WO$_{3-x}$ surface, while the stronger adsorption energy reveals longer recovery time in the sensing test [50]. The same mode was applied to calculate the differential charge densities (Figs. 8(e) and 8(f)), indicating that the neighboring Fe site acts as an electron donor, promoting the electron transfer from WO$_3$ to the adsorbed geranyl acetone at the W site.

3. 4   Practicability application

The practicability application potential for the gas sensors prepared in this work was assessed under different storage conditions. During the storage process, the amount of released geranyl acetone molecules will decrease as cooked rice is prone to undergoing redox reaction and deterioration [4]. Herein, we combined the optimized 3% Fe–WO$_{3-x}$ gas sensor with homemade gas

sensing equipment to detect VOCs released from cooked rice, and the correlation diagrams are shown in Figs. S10 and S11 in the ESM. The response/recovery curves of the 3% Fe–WO$_{3-x}$ gas sensor towards cooked rice under storage conditions at different duration (0, 6, 12, 18, and 24 h) are depicted in Figs. 9(a)–9(e). The response value decreased from 7.76 to 1.78 with longer storage time (Fig. 9(f)). For evaluating the freshness in different periods of cooked rice storage, according to the correlation between the concentration of the target gas and the response value of the 3% Fe–WO$_{3-x}$ gas sensor, X volatilized from freshly cooked rice is about 3.75 ppm, of which with the prolonging of storage time, the VOC concentration will decline to the ppb level [51], which indicates that remaining cooked rice is highly spoiled after 24 h storage. Furthermore, the chemical reactions in cooked rice will decelerate under lower storage temperatures, resulting in few volatile oxidative products generated in cooked rice [2]. Therefore, the condition of the cooked rice storage at a low temperature was carried out (Fig. 9(f)). Cooked rice was stored at room temperature (25±2 ℃) and at a low temperature (−5±2 ℃) for 18 h, which demonstrated that the response value of the sensor corresponds to

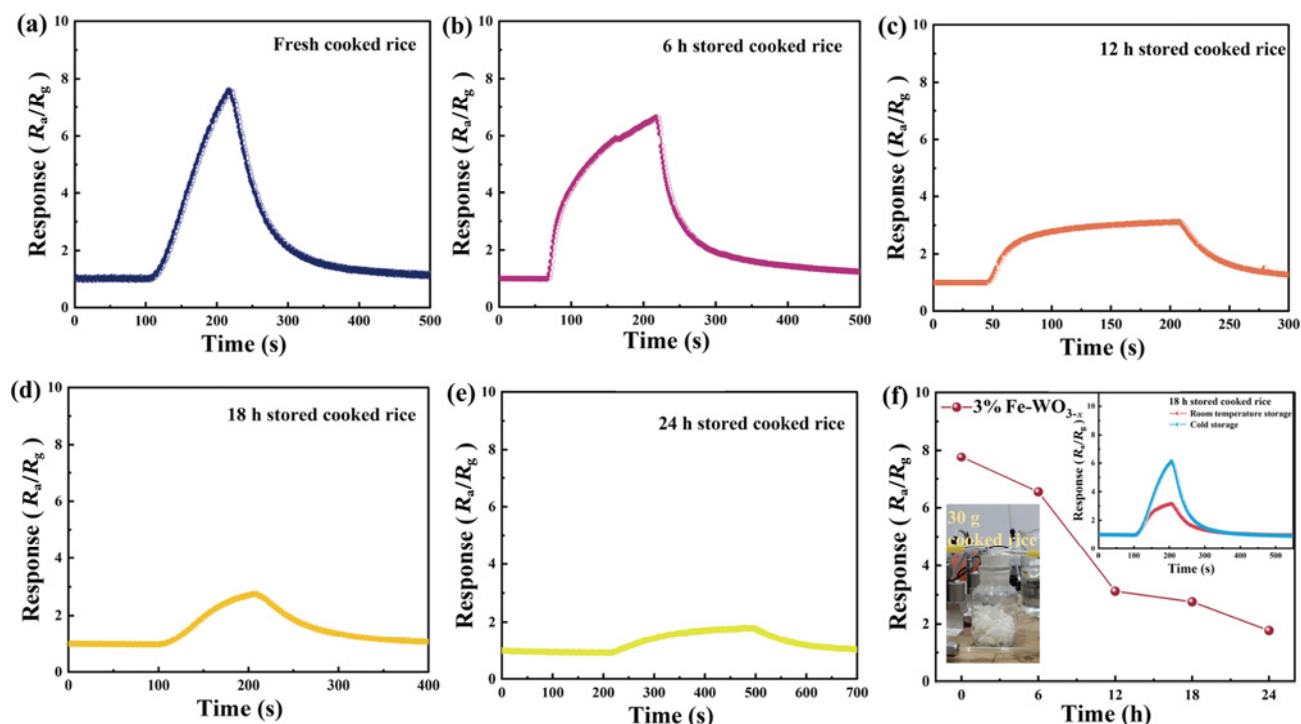

Fig. 9 (a–e) Response curves of 3% Fe–WO$_{3-x}$ gas sensor towards released gases from 30 g cooked rice during different stages (0, 6, 12, 18, and 24 h); (f) response values of 3% Fe–WO$_{3-x}$ gas sensor towards released gases from 30 g cooked rice during different stages (0, 6, 12, 18, and 24 h) (the inset in the top right corner is response curves of 3% Fe–WO$_{3-x}$ gas sensors towards released gases from 30 g cooked rice during 18 h storage condition at room temperature and a low temperature).

3.13 and 6.10, respectively, indicating that cooked rice at a low temperature possessed a higher degree of freshness. Therefore, the 3% Fe–WO$_{3-x}$ gas sensor possessed the promising potential for the detection of geranyl acetone and the quality inspection of cooked rice.

4   Conclusions

In conclusion, a novel and reliable geranyl acetone sensor based on WO$_3$ was created by a facile and economical solvothermal method. Fe ions were doped with WO$_3$ nanoparticles for high-performance geranyl acetone detection, and the response value is 7 times that for the WO$_3$ nanoparticles without Fe modification. The composite sensors presented outstanding response (2.42–82.7) toward 2–10 ppm geranyl acetone with low LOD (237 ppb), short τ_{res}/τ_{rec} (41 s/480 s) at room temperature, excellent selectivity, outstanding reproducibility, and long-term stability within 30 d. Strengthened sensing properties primarily contributed to the reduction in D, generous oxygen defects, advanced specific surface area, and promoted charge separation capacity of the fine-controlled Fe-doped WO$_{3-x}$. Additionally, the as-fabricated sensors were employed for geranyl acetone detection in cooked rice to verify the practicability application prospect in food spoilage monitoring. The multiple integrations of Fe-doped WO$_{3-x}$ composites with other materials on the platform will be dealing with identifying multiple characterizing VOCs released from diverse food. Above all, the as-prepared gas sensor could be applied for rapid, precise, and reliable monitoring of geranyl acetone, which can facilitate the taste quality of cooked rice and is expected to be extended to cooked rice and other food detection for quality inspection.
